# Memory Management

(1)

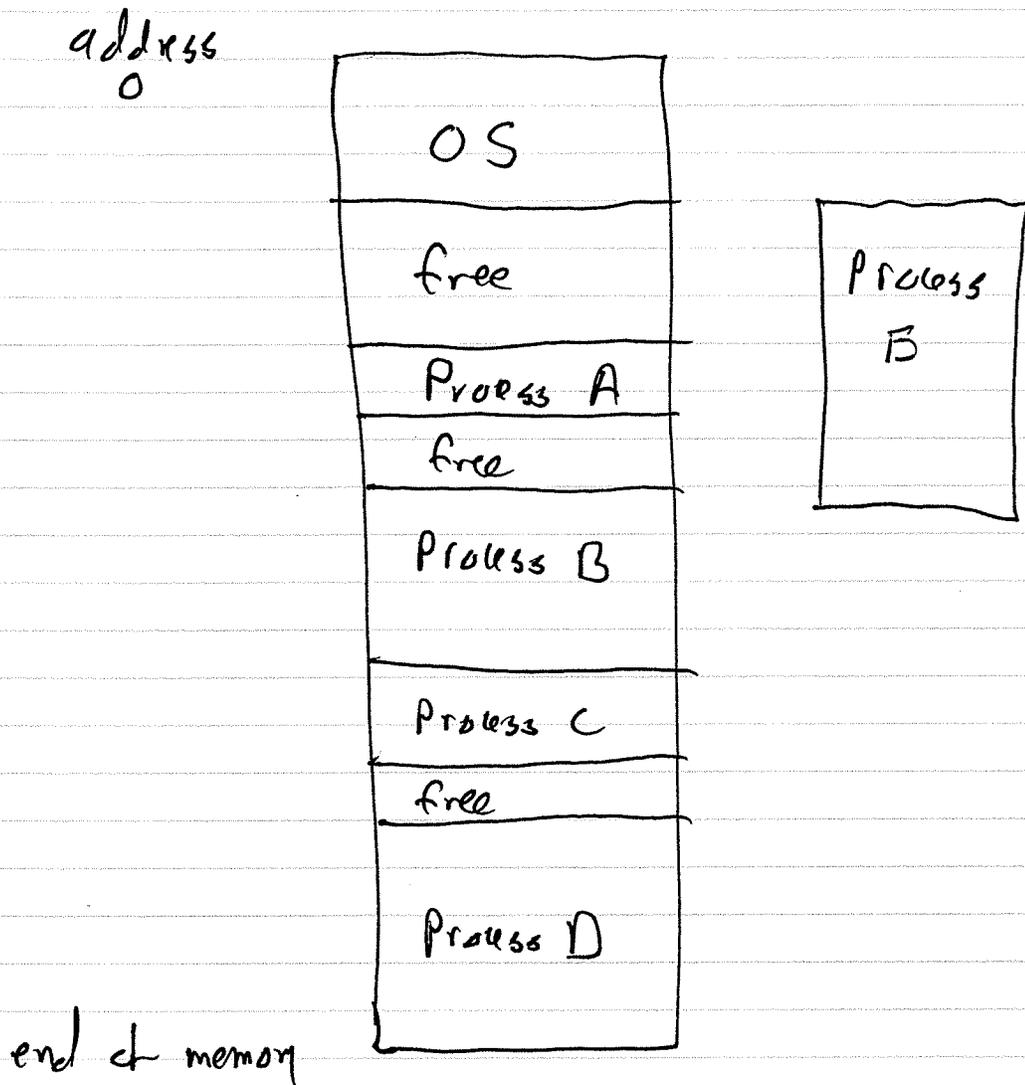

A process' View of memory:

It "thinks" it "owns" all of memory and it "thinks" its address space begins at location  $\emptyset$

(2)

The reality :

Assume: - A process' memory is contiguous

- Different process' use different amounts of memory

(3)

- The OS places a process where it "fits"

There's enough free space to run process B, but this space isn't contiguous.

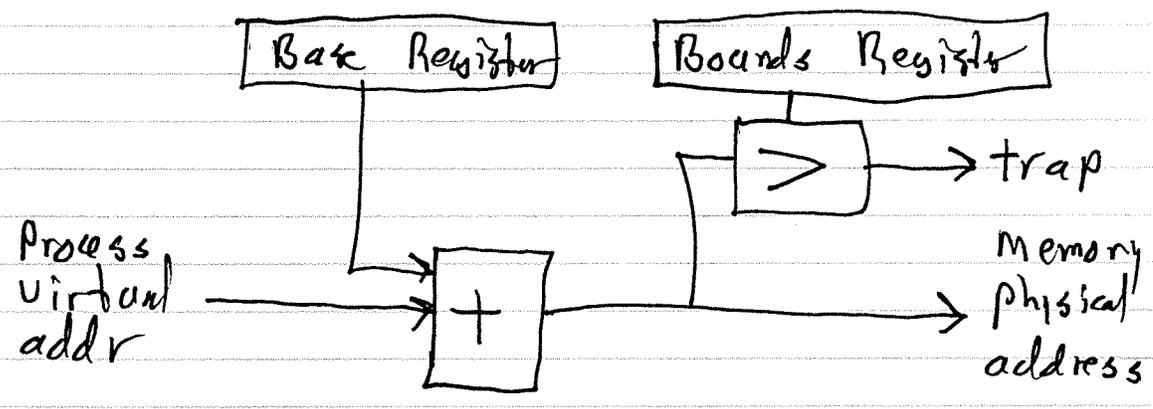

To virtualize memory  
(make a process think its view is reality)

we must:

- Translate a process' address (virtual) to memory's physical address
- prevent process' from "scribbling" on each other's memory
- Be able to coalesce free space
  - Relocate process'
- Be efficient

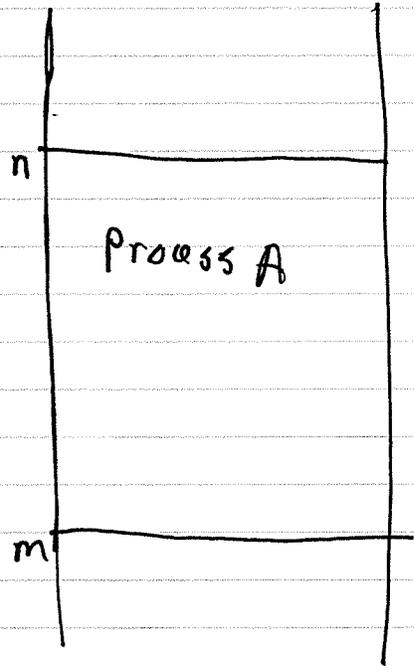

The simple solution :

Base + Bounds registers in  
the CPU and an adder  
(mmu)

Example :

Base Register  
is set to  $n$   
and Bounds  
register is  
set to  $m$   
when A runs

A is  
allocated  
 $n$  to  
 $m-1$

5

Let's say

$$n = 1024$$

$$m = 2048$$

| Virtual address | Physical address        | Trap |
|-----------------|-------------------------|------|
| 0               | <del>1024</del><br>1024 | n    |
| 42              | ?                       | ?    |
| 2100            | ?                       | ?    |
